ABSTRACT

The present investigation was conducted to study the genetic variability, correlation and path coefficient analysis for eight yield and yield attributing traits in 47 (40 improved parental lines + 7 checks) lines of rice. Analysis of variance revealed significant differences among all the treatments under study. High values of PCV and GCV were recorded for traits like number of filled grains per panicle and single plant yield while moderate PCV and GCV recorded for plant height, number of productive tillers per plant, spikelet fertility and 1000 grain weight. High heritability coupled with high genetic advance as percent of mean was observed for the traits namely number of filled grains per panicle, plant height and single plant yield. The traits *viz*., productive tillers per plant, panicle length, number of filled grains per panicle, spikelet fertility % and 1000-grain weight exhibited significant and positive association with single plant yield. Number of filled grains per panicle, 1000-grain weight, number of productive tillers per plant, plant height and panicle length exhibited positive direct effect on single plant yield indicating that direct selection for these traits would lead to improvement in single plant yield.

1. INTRODUCTION

Rice (*Oryza sativa* L.) is the primary staple food for one third of the world population and is often referred as "Global Grain" [1]. "It constitutes approximately 20% of the global dietary energy supply, making it a significant contributor in meeting the world's nutritional needs. Rice production and research have encountered significant challenges in recent times. Some major rice-producing nations have experienced a plateau in yield and total production for many years" [2]. "In the current scenario, rice productivity is increasing at a rate of 1% per year which is less than the required rate of 2.4% per year to double global production by 2050" [3]. To meet the increased demand, many countries are actively seeking to leverage hybrid rice technology, which has the potential to enhance rice production and productivity. Restorer lines play a crucial role in hybrid rice breeding and by enhancing restorer lines, breeders can introduce greater genetic diversity into hybrid development, resulting in the creation of superior hybrids.

Grain yield is influenced by various component traits, with some directly impacting yield and others exerting indirect effects. Hence, to enhance grain yield, it is essential to identify the traits that directly or indirectly contribute to it. In such conditions a comprehensive study on the genetic variability of a population, character association and the path coefficient analysis for the grain yield and its attributing traits play a crucial role in improving crop productivity [4]. "The phenotypic coefficient of variation (PCV) and genotypic coefficient of variation (GCV) provide an idea about the magnitude of variability. Heritability estimates along with genetic advance are more helpful in predicting the genetic gain under selection. Analyzing correlations between crop yield and its attributing traits offers valuable insights towards the relationship between yield and its components" [5]. Path analysis also helps with the identification of the direct and indirect reasons of association and the creation of effective breeding plans for the improvement of genotypes. Therefore, the present investigation was carried out with the aim of assessing the variability parameters, character association and path coefficient analysis for grain yield and its attributing traits.

2. MATERIALS AND METHODS

The research was carried out during *kharif,* 2022 at Research farm, ICAR- Indian Institute of Rice Research (IIRR), Hyderabad, located at an altitude of 542 m above mean sea level on 17° 19" N latitude and 78° 23" E longitude in Southern Zone of Telangana State.

The material for the present genetic study comprised of 47 entries of which 40 are improved parental lines derived from the cross between AR 9-18 and yield enhancing donor YPK 198, through forward breeding, seven checks *i.e.*, four maintainer lines (APMS6B, IR58025B, IR79156B, CRMS32B), two parents (AR 9-18, YPK 198) and a national check (CR-DHAN-201). The experiment was laid out in randomized complete block design (RBD) in two replications.

Phenotypic data was recorded for eight yield and its attributing traits *viz.*, days to 50% flowering, plant height (cm), number of productive tillers per plant, panicle length (cm), spikelet fertility (%), number of filled grains per panicle, weight of 1000 grains (g) and single plant yield (g) on all the lines based on flowering duration and maturity. During the experiment to raise a healthy nursery and main crop, the recommended cultural practices and essential crop protection measures were implemented.

Statistical analysis was done for the data recorded on eight yield and its attributing traits *viz.*, genotypic coefficient of variation (GCV), phenotypic coefficient of variation (PCV), broad sense heritability and genetic advance as per cent of mean. GCV and PCV were determined using the method described by Burton and Dewane [6]. The range of variability was categorized as follows: high (> 20%), moderate (10-20%) and low (< 10%) in accordance with the classification proposed by Sivasubramanian and Madhavamenon [7]. Lush [8] and Hanson *et al.* [9] proposed that broad sense heritability h^2(bs) was determined by taking the ratio of genotypic variance to the total variance and expressed in per cent. As per the classification proposed by Robinson *et al.* [10] heritability estimates were categorized into three groups: high (> 60%), moderate (30-60%) and low (0-30%).

Genetic advance was calculated and then categorized into different levels: high (> 20%),

moderate (10-20%) and low (< 10%) as suggested by Johnson *et al.* [11]. For the calculation of simple correlations, the formula given by Weber and Moorthy [12] was used while for computation of path analysis, the method described by Dewey and Lu [13] was utilized.

3. RESULTS AND DISCUSSION

The analysis of variance (ANOVA) indicated that the mean sum of squares due to genotypes was highly significant for all the characters, which further ascertain that there is considerable amount variability in the material and ample scope for improvement in the investigated traits (Table 1).

The phenotypic coefficient of variation (PCV) and genotypic coefficient of variation (GCV) provide an idea about the magnitude of variability. Number of filled grains per panicle (28.91% and 26.54%) and single plant yield (24.13% and 21.12%) recorded high PCV and GCV values (Table 2, Fig. 1), indicating the presence of considerable variability thus selection may be useful for improvement of these traits. Similar results were reported by Hasan-Ud-Daula and Sarker [14]. In variability studies, moderate PCV and GCV were recorded for Plant height, number of productive tillers per plant, spikelet fertility and 1000 grain weight as observed by Sandeep *et al.* [15] and Singh *et al.* [16] for plant height, productive tillers per plant, 1000-grain weight and Tiwari [17] for spikelet fertility. Panicle length recorded moderate PCV and low GCV, similar results were reported by Ali *et al.* [18]. Low PCV and GCV estimates were exhibited by days to 50% flowering. These findings are consistent with the results reported by Singh *et al.* [19]. The slight disparities reported between phenotypic coefficient of variation and genotypic coefficient of variation on most traits imply the presence of sufficient genetic variability for those traits, which could facilitate selection. Number of filled grains per panicle (84.24% and 50.17%), plant height (77.4% and 22.67%) and single plant yield (76.56% and 38.06%) recorded high heritability and high genetic advance as a percentage of the mean (Table 2, Fig. 2). This indicates the presence of additive gene action thus selection may be effective for these traits. These results align with the findings of Lakshmi *et al.* [20], Kiruthikadevi *et al.* [21], Patra *et al.* [22], Kumar *et al.* [23] and Nath and Kole [24]. The traits spikelet fertility (73.30% and 18.28%) and 1000 grain weight (65.15% and 17.23%) exhibited high

heritability with moderate genetic advance as a percentage of the mean, as reported by Hassan *et al.* [25] and Awad *et al.* [26] whereas, days to 50% flowering (71.30% and 7.41%) showed high heritability with low genetic advance as percent of mean as that reported by Dhavaleshvar *et al.* [5]. Moderate levels of heritability and genetic advance as percent of mean were recorded for number of productive tillers per plant (40.40% and 14.12%) and panicle length (55.42% and 14.79%) which are in accordance with the results of Parvathi *et al.* [27] and Singh *et al.* [19].

At phenotypic level, number of productive tillers per plant (0.382**), panicle length (0.238*), number of filled grains per panicle (0.619**), spikelet fertility % (0.232*) and 1000-grains weight (0.604**) exhibited significant and positive association with single plant yield. Hence, direct selection for these characters would improve the yield wherein, other yield components *viz.,* days to 50% flowering (0.032), plant height (0.073) have shown positive non-significant association (Table 3). Similar results were reported by Santhipriya *et al.* [28] and Singh *et al.* [19] for single plant yield with number of productive tillers per plant, panicle length and 1000-grain weight; Saha *et al.* [29], Kiruthikadevi *et al.* [21], Shrivatsav *et al.* [30], Hasan-Ud-Daula and Sarker [14] for number of filled grains per panicle; Shrivastav *et al.* [30] and Buelah *et al.* [31] for spikelet fertility %.

Considering grain yield as effect and other quantitative traits as causes the correlation coefficient between grain yield per plant and various component characters were partitioned into measures of direct and indirect effects through path analysis. It was observed that the direct and indirect association through other characters by path analysis revealed that number of filled grains per panicle (0.4495) exhibited highest positive direct effect on single plant yield (Table 4, Fig. 3) followed by 1000 grain weight (0.3778), number of productive tillers per plant (0.2006), plant height (0.0503) and panicle length (0.0105) while the trait days to 50% flowering (-0.0809) exhibited negative direct effect followed by spikelet fertility (-0.0277). These results are in accordance with Kiruthikadevi *et al.* [21] for filled grains per panicle, 1000-grain weight, productive tillers per plant and panicle length, Gunasekaran *et al.* [32] and Devi *et al.* [33] for plant height. The residual effect of path coefficient analysis was 0.6475. The high residual effect value may be attributed to the effects of additional characters not included in this study.

4. CONCLUSION

The estimates of PCV and GCV were notably high for traits such as number of filled grains per panicle and single plant yield implying that direct selection for these traits may lead to genetic improvement. Furthermore, it was noted that for traits like plant height, number of filled grains per panicle and single plant yield both high heritability and a substantial genetic advance as a percentage of the mean were recorded. This indicates the predominance of additive gene action in their genetic control. Through correlation and path coefficient analysis, it was evident that among the examined yield traits, characters such as number of filled grains per panicle, 1000-grain weight, productive tillers per plant, panicle length were considered as most critical ones as they exhibited higher correlation coefficients and direct effects in association with single plant yield.
